Abstract

Microbial growth on the skin and organ surfaces is a common problem associated with formaldehyde fixation of animal cadavers and is especially so following watering of cadavers prior to dissection. Cadavers of three sheep, one goat and three horses were fixed with a solution of 2% formaldehyde, 30% ethanol, and 20% polyethylene glycol 400. At time intervals tissue samples of; skeletal muscle, lung and intestine were analyzed for cultivable aerobic bacteria, anaerobic bacteria and fungi. The aim of this study was to evaluate the effectiveness of a novel cadaver fixative solution having a 2% formaldehyde concentration. Visual examination of each fixed cadaver's skeletal muscles and visceral organs showed that these had retained a relatively natural appearance. No yeast or mould was cultured. Anaerobic bacteria namely *Clostridium sporogenes*

and *C. tyrobutyricum* were isolated from the muscles of two sheep. The aerobic bacterium *Bacillus licheniformis* was cultivated from the colon and duodenum of all three horses 40 days post fixation.

Keywords: Anatomy, dissection, embalming, formaldehyde, polyethylene glycol

Introduction

Animal cadavers remain a core-teaching tool for anatomists and veterinary medical educators teaching gross anatomy. Worldwide there have been a large number of individual embalming fluid formulations containing a great variety of; fixatives, disinfectants, surfactants, buffers, dyes, glycerol and salts used in the preparation of cadavers for dissection. Evaluations of these formulations have mostly focused on the

aesthetics, both visual and tactile, of the fixed specimens. Few studies report on the disinfectant efficacy of the embalming fluids.

Historically most successful cadaver fixatives have been based on formaldehyde, a commonly used industrial fungicide and germicide. Even today, its antioxidant activity and ability to prevent microbial growth makes it popular for the preparation and preservation of human (Balta *et al.*, 2015, Brenner, 2014) and animal cadavers (Janczyk *et al.*, 2011b, Silva *et al.*, 2007).

However, there are potential health risks associated with either exposure to high concentrations of formaldehyde or of long-term exposure to low concentrations of formaldehyde (IARC, 2006). This risk is low for students studying anatomy because their usual exposure is 2 - 5 hours per week for 1 - 4 semesters of about 12 weeks each semester. However, for preparatory staff and academics handling specimens for longer periods, often over tens of years the risks are greater (IARC, 2006, Wantke *et al.*, 2000). It is well known that formaldehyde affects not only the external contact surface of the body notably the skin and eyes but also causes irritation to the mucous membranes in the nose and throat (Chia *et al.*, 1992, Dixit *et al.*, 2005, Kim *et al.*, 2002, Tanaka *et al.*, 2003). In some individuals, even a brief exposure to concentrations of formaldehyde as low as 0.1 to 2 ppm may cause coughing, nausea, as well as burning sensations in the eyes, nose

and throat. Formaldehyde is known to have irritant effects on the respiratory tract and may induce adverse alterations in pulmonary function parameters and cellular morphology (IARC, 2006, Kriebel *et al.*, 1993, Wantke *et al.*, 2000). Chronic exposure has been linked to different types of cancer particularly those that involve the upper airway (Kerns *et al.*, 1983). The U.S. Environmental Protection Agency (EPA) classified formaldehyde as a probable human carcinogen under conditions of unusually high or prolonged exposure (Agency, 1989).

Over many decades the maximum allowable concentration (MAK value) of formaldehyde fumes within the workplace has decreased from 0.5 ppm in 1989 to that recommended by the Senate Committee of the Deutsche Forschungsgemeinschaft as 0.3 ppm (NIH, 2009). The corresponding MAK value in the United States of America is 0.75 ppm and in Japan it is 0.1 mg/m³ (Abdul-Wahab *et al.*, 2015, Barsan, 2007). Consequently, over that timeline reducing the formaldehyde concentration in embalming fluid has become a major focus for anatomists to ensure a safe workplace for students and staff that regularly handle or dissect preserved cadavers.

Numerous embalming formulations have been developed with the aim of reducing the harmful effect of exposure to formaldehyde, but each has its own shortcomings such as; limited

preservation life, undesirable microbial growth, tissue yellowing, damage to the anatomical texture of the tissue and in some instances high cost (Al-Hayani *et al.*, 2011, Hammer *et al.*, 2012, Macdonald and Mac Gregor, 1997). All of these limitations lessen their suitability for the long-term preservation and use of cadavers in anatomical dissections.

The use of non-formaldehyde based embalming solutions such as N-vinyl-2-pyrrolidone (Haizuka *et al.*, 2018), nitrite pickling salt (Janczyk *et al.*, 2011a), polyhexamethylene guanidine hydrochloride (Anichkov *et al.*, 2011) and dry shellac (Al-Hayani *et al.*, 2011) have been and are being examined extensively. Fixatives like N-vinyl-2-pyrro-lidone, polyhexamethylene guanidine hydrochloride were successful in preserving soft, elastic internal organs and a carcass with moderate joint motility. The other formaldehyde alternatives like nitrite pickling salt and shellac failed due to their causing the cadavers to be an unnatural colour and being corrosive (Al-Hayani *et al.*, 2011, Anichkov *et al.*, 2011, Haizuka *et al.*, 2018, Janczyk *et al.*, 2011a). Additional procedures such as rinsing cadavers in water before handling and engineering laboratory airflow to quickly remove cadaver fumes away from the breathing zone in dissection halls are used to reduce exposure to formaldehyde (Coleman and Kogan,

1998, Coskey and Gest, 2015, Janczyk *et al.*, 2011a, Turan *et al.*, 2017). Janczyk *et al.* (2011b) recommended that gas masks should be worn by those handling large animal cadavers held in formalin baths. Whilst anatomists have attempted to reduce formaldehyde exposure by watering formaldehyde-fixed cadavers prior to dissection, this practice is associated with microbial growth on the skin and organ surfaces (Janczyk *et al.*, 2011b). To the best of our knowledge recent studies of new embalming solutions have not assessed the nature and effects of microbial growth isolated from formaldehyde preserved animal cadavers (Balta *et al.*, 2015, Janczyk *et al.*, 2011b, Turan *et al.*, 2017). The aim of this study was to evaluate the effectiveness of a novel cadaver fixative with formaldehyde concentrations reduced to 2 percent. Our evaluation conducted on sheep, goat and horse cadavers included; assessing microbial and fungal growth inhibition, plus the pre- and post-embalming macroscopic assessment of muscles and internal organs. These evaluations were compared with species matched dissections of unfixed fresh specimens. However, the fresh cadaver dissections were undertaken over two days only.

The concentration of formaldehyde fumes in the air at working heights

was assessed in the veterinary anatomy dissection hall of the Free University of Berlin.

Material and Methods

Animal cadaveric specimens

A total of seventeen adult animals i.e. six horses (200 to 300 kg), eight sheep (40 to 50 kg), and three goats (35 kg) were euthanased by a veterinarian in accordance with all relevant local animal welfare laws, guidelines, and policies (Landesamt für Gesundheit und Soziales Berlin). After the animals were anaesthetised, the left common carotid artery was catheterised for exsanguination. Three horses, three sheep, and a goat were subsequently fixed. The other three horses, five sheep and two goats were retained as fresh non-fixed cadavers.

Formaldehyde based and other fixatives/preservatives

To preserve the animal cadavers, a fixative solution consisting of 2% formaldehyde, 30% ethanol and 20% polyethylene glycol 400, topped up with tap water to 100% was infused via the carotid artery using a peristaltic pump (MA-1450 Perfu-Tek, Medis GmbH, Germany).

Approximately 9 L/ sheep or goat and 60 L/ horse of fixative were used. The cadavers of small ruminants were sealed in plastic bags and

stored in a supine position at 5° Celsius until the bags were opened on the day of dissection. Horses were fixed in a standing position and stored at 5° Celsius. Plastic bags were wrapped around the horse cadavers in the cold room to reduce any evaporation of the preservative fluid. Dissection of the horse cadavers was carried out twice weekly by students and veterinary educators over a period of five months. A solution of 30% ethanol and 20% polyethylene glycol made up to 100% with tap water was applied to all surfaces exposed by dissection on the cadavers after each dissection to prevent the cadavers from drying out when they were stored in the cold room.

As the dissections progressed, embalming parameters such as palpable consistency, muscle and joint flexibility, color, tissue hydration, and odour were assessed weekly after each dissection through a subjective assessment and palpation by preparatory and academic staff.

Major structures evaluated included; skeletal muscle in the field of dissection, then heart, lung, liver, spleen, kidney, stomach, small and large intestine, peripheral nerves and blood vessels as the dissections proceeded.

During the dissections of the fresh non-fixed cadavers (three horses, five sheep and two goats), the same

parameters that were applied to evaluate the dissections of the fixed cadavers were used.

Aerobic and anaerobic culture of cadaveric specimens

Microbial investigations were conducted on tissue biopsies (2x2 cm) of the superficial cervical trapezius muscle, deep within the longissimus thoraces muscle, superficial and deep biopsies of the cranial and middle parts of the left caudal lobe of the lung as well as tissue samples of the duodenum and descending colon. In all species, biopsies were taken 10 and 40 days after dissection commenced. In the horses, these were at 10 and 40 days post fixation whilst in the small ruminants biopsies were taken at 75 and 105 days post fixation. The samples were stored in clear, lidded, plastic tubes and the microbiological examination was performed according to standard procedures (Murray *et al.*, 2007).

Determination ambient formaldehyde fumes concentrations

Formaldehyde fumes in the air of the anatomy dissection laboratory were measured at one and three months after embalming. Here Formaldehyde-0.1 Detector Tubes (MSA Auer GmbH, Berlin, Germany) were placed in the breathing zone (0.5 meter above and at the side of animal-cadavers). Air samples were col-

lected by attaching the Formaldehyde-0.1 Detector Tube to Kwik-Draw Deluxe Detector Tube Pump (MSA Auer GmbH, Berlin, Germany). After sampling, the formaldehyde concentration was read directly from the scale printed on the tube.

Results

Dissection parameters

The weekly observations of the student's dissections show that the visual appearance of the cadavers remained close to their natural appearance. The muscles and fasciae retained most of their natural color and texture in the horses (Fig 1A) but the skeletal muscles of the small ruminant cadavers appeared lighter than their natural colour. However, the muscles of all the cadavers developed a darker colour towards the end of the study period. This manifestation was more marked in horses than in the small ruminants. On palpation, the skeletal muscles of all cadavers were flexible and easy to dissect. However, the range of movement of the joints were limited and rigid when compared with fresh cadavers. All gross anatomical structures including arteries, veins and nerves were distinguishable and easy to dissect in all animals.

In all cadavers, the thoraco-abdominal organs such as the heart, lung, liver, spleen and kidneys were more rigid and had a darker hue than those in a non-fixed state (Fig 1B, C,

D). The stomach, small and large intestines had an anatomic appearance close to that of non-fixed cadavers. Blood vessels and nerves were readily palpated and could be dissected easily. The adipose tissue had lost its normal colour as seen in freshly killed animals and had turned a light shade of gray.

Microbial analysis

In the current study, fungi were not cultured from any of the samples taken from the fixed cadavers. However, anaerobic bacteria, *Clostridium sporogenes*, and *C. tyrobutyricum* were isolated from the cervical trapezius muscle of two sheep. *Paenisporsarcina* sp. was cultured from the thoracic longissimus muscle of one horse. Similarly, *Paenibacillus* sp. was cultured from the colon of one horse, and *Bacillus* sp. was cultured from the duodenum of the goat. Colonies of the *Bacillus licheniformis* were cultured from the duodenum and colon of all horses.

Concentration of ambient formaldehyde fumes

The concentration of formaldehyde fumes measured in the breathing zone ranged from 0.05–0.15 mg/m³

Discussion

Ideally embalming fluids should maintain the natural colour and texture of the tissues and organs

(Coleman and Kogan, 1998) and should also prevent microbial growth over the time period of the anatomical dissection (Brenner, 2014). Historically, high concentrations of up to 10% of formaldehyde have been used in embalming fluids to prevent microbial growth however this has many adverse side-effects including rigidity and colour changes to the cadaver's tissues and organs (Brenner, 2014, Hammer *et al.*, 2012, Silva *et al.*, 2007).

In the current study, an embalming fluid consisting of; formaldehyde (2%), ethanol (30%), and polyethylene glycol 400 (20%) made up by tap water to 100%, was perfused via the left carotid artery into three sheep, one goat and three horses. In the fixed horses, muscle colour was similar to that of non-fixed horses but in the small ruminants, the muscles were slightly paler in colour than found in non-fixed ruminants. On palpation, the somatic muscles and joints of the fixed cadavers were a little more rigid than found in non-fixed cadavers. Similarly, the organs of all animals were more rigid and darker in colour than found in non-fixed cadavers.

According to Pretorius (1995) tissues preserved using higher concentration of formaldehyde (12%) resulted in marked rigidity, which was ideal for

tissue slicing but is not ideal for anatomy students who prefer tissue pliability and texture similar to that of the in-vivo state. Our study using a fixative solution at far lower concentration of formaldehyde (2%) resulted in modest tissue flexibility. These results are consistent with the results of (Silva *et al.*, 2007) where they used low formaldehyde concentrations (0.3%) and reported that their dog cadavers were suitable for surgical training of veterinary medicine students.

This study used PEG, a polymer of ethylene oxide that acts as an osmotic laxative by binding water thus lessening desiccation to maintain the flexibility of muscles and organs. Fortunately, there are no known adverse health effects of PEG, and even if it is ingested, it is inert and not metabolized within the gastrointestinal tract (Brenner, 2014, Chassagne *et al.*, 2017, Moore *et al.*, 2008). Polyethylene glycol 400 in combination with ethanol serves to preserve moisture in embalmed cadavers (Bradbury and Hoshino, 1978) and to act as an inhibitor of mould growth (Macdonald and Mac-Gregor, 1997). The fixative and preservation properties of PEG and ethanol together kept cadavers free of mould and reduced bacterial loads (Steinmann, 1982). Similarly, the combination was used for the same purpose in the preservation flu-

ids developed by Thiel, where embalming fluids were based on low concentrations of formaldehyde (1.4%) (Thiel, 1992a, b, 2002). The results of our study confirm the disinfectant properties of the embalming solution used in this study for embalming cadavers (Table 1).

In the present study, *Clostridium sporogenes* and *C. tyrobutyricum* were isolated from skeletal muscles of two sheep cadavers. Both organisms are anaerobic Gram-positive bacteria that are usually found in soil and only colonize animals as part of the normal saprophytic flora where they have a symbiotic rather than a pathogenic interaction with the host (Logan and De Vos, 2009). Whilst *C. tyrobutyricum* is found commonly in soil, it has been isolated from silage, milk, and spoilt cheese (Bergere and Lenoir, 2000, Bergère and Sivelä, 1990). The *C. sporogenes* and *C. tyrobutyricum* cultured from animal cadavers are most likely environmental saprophytic contaminants that proliferate following death (Logan and De Vos, 2009).

In this study, the *Paenisporosarcina* sp. isolated from the thoracic longissimus muscle of a horse is a gram positive, aerobic, spore-forming, rod-shaped bacterium mostly isolated from soil (Krishnamurthi *et al.*, 2009). This *Paenisporosarcina* sp. is most likely an environmental saprophyte.

Colonies of the aerobic *Bacillus licheniformis* were cultivated from the duodenum and colon in all horses. In addition, *Paenibacillus sp.* was cultured from the colon of one horse, and *Bacillus sp.* cultured from the duodenum of the goat. *Bacillus licheniformis* is one of the most ubiquitous species of its genus and has been isolated from raw milk and along the dairy processing continuum (Kalogridou-Vassiliadou, 1992, Scheldeman *et al.*, 2006). *Bacillus licheniformis* has become increasingly recognized as a human pathogen causing sepsis, mainly in immunocompromised patients (Blue *et al.*, 1995, Haydushka *et al.*, 2012, Ozkocaman *et al.*, 2006). Whilst the organisms isolated in this study are probably innocuous saprophytic bacteria proliferations in the animal cadavers, their potential pathogenic nature warrants specific safety precautions to avoid accidental transmission from cadavers to humans. Historically the use of formaldehyde at concentrations of up to 10% was used commonly to embalm cadavers worldwide (IARC, 2006, Kunz and Wilcke, 1991, Lischka *et al.*, 1979). This resulted in humans being exposed to formaldehyde fumes possibly adversely affecting their health (IARC, 2006, Wantke *et al.*, 2000). The main concern with formaldehyde is long term exposure to its fumes causing irritation to the mucous

membranes in the nose and throat, difficulty in breathing, asthmatic symptoms, leukaemia and rarely nasal sinus cancer and nasopharyngeal cancer (IARC, 2006). In today's world, embalming of specimens for the teaching of veterinary anatomy has moved away from using high concentrations of formaldehyde to alternate formulations using low concentrations of formaldehyde, around 2%, or even no formaldehyde (Elnady, 2016, Janczyk *et al.*, 2011b, Lombardero *et al.*, 2017, Steinke *et al.*, 2008, Turan *et al.*, 2017). Other than reducing the concentration of formaldehyde used in embalming fluids, exposure levels to formaldehyde fumes can be reduced by improved air ventilation and maintaining the room temperature below 19 °C (Janczyk *et al.*, 2011b). Designing dissection facilities to have laminar airflow from the ceiling down past the breathing zone to extraction at floor level has been adopted extensively (Coleman, 1995, Coleman and Kogan, 1998, Martin *et al.*, 1995). Simply ensuring that handling and dissection of cadavers at 19°C or lower, considerably lessens the concentration of formaldehyde fumes as the boiling point of formaldehyde is 19 °C (Janczyk *et al.*, 2011b). In this study the concentration of formaldehyde fumes measured in the breathing zone was found to be 0.05–0,15 mg/m³ which is lower than

0.3 ppm, the Maximum Allowable Concentration stipulated by the German Research Foundation (NIH, 2009). These results confirm the results of Whitehead and Savoia (2008), who found that levels of formaldehyde vapours in the dissecting laboratory can be reduced up to 50% by using embalming fluid with a 2% formaldehyde concentration. Fixation using low formaldehyde concentrations in combination with ethanol and polyethylene glycol inhibits microbial growth on animal cadavers, appears to pose little health risk and, is environmentally friendly, cost effective, and results in cadavers having near natural colour and texture of their tissues and organs.

Acknowledgement

We wish to thank Professor Johanna Plendl from the Institute of Veterinary Anatomy, Department of Veterinary Medicine for all her help and guidance. We would like to thank Ms. Janet Weigner and Mr. Florian Grabitzky for their help in the collection of the samples. We would like also to thank Dr. Antina Lübke-Becker for her help in microbial culture of the samples.
